Programming for Scientists

Exceptions and exception handling

Lecture outline

* **The exception mechanism in python**
* Raising exceptions (`assert` and `raise`)
* Catching exceptions

Reminder: Kinds of errors

1. Syntax errors: it's not python!

2. Runtime errors – code is syntactically valid, but you're asking the python interpreter to do something impossible.
   - E.g., apply operation to values of wrong type, call a function that is not defined, etc.
   - Causes an *exception*.

3. Semantic/logic errors: code runs without error, but does the wrong thing (for example, returns the wrong answer).

Exceptions

* Exceptions are a control mechanism for handling runtime errors:
  - An exception is *raised* when the error occurs.
  - The exception moves up the call stack until it is *caught* by an *exception handler*.
  - If no handler catches the exception, it moves all the way up to the python interpreter, which prints an error message (and quits, if in script mode).
* python allows the programmer to both raise and catch exceptions.

Exception names

* Exceptions have *names*:
  - `TypeError`, `ValueError`
    (incorrect type or value for operation)
  - `NameError`, `UnboundLocalError`,
    `AttributeError`
    (variable or function name not defined)
  - `IndexError` (invalid sequence index)
  - `KeyError` (key not in dictionary)
  - `ZeroDivisionError`
  - ...and others.

* `https://docs.python.org/3/library/exceptions.html#concrete-exceptions` for full list of exceptions in python standard library.
* Modules can define new exceptions.

Lecture outline

- ⋆ The exception mechanism in python
- ⋆ **Raising exceptions (`assert` and `raise`)**
- ⋆ Catching exceptions

Assertions

* `assert` *condition*, `"fail message"`
  - Evaluate *condition* (to type `bool`)
  - If the value is not `True`, raise an
    `AssertionError` with the (optional)
    message.

* Assertions are used to check the programmer's
  assumptions (including correct use of functions).

* Function's docstring states assumptions;
  assertions can check them.

The `raise` statement

* `raise ExceptionName(...)`
  - Raises the named exception.
  - Exception arguments (required or optional) depend on exception type.

* Can be used to raise any type of runtime error.
* Typically used with programmer-defined exception types.

Reminder: Defensive programming

- ⋆ Runtime errors are preferrable to semantic errors, because it is immediately clear when and where they occur.
- ⋆ It is better to "fail fast" (raise an exception) than to return a non-sense result.
- ⋆ Don't assert more than necessary. For example,

```
def fun(seq):
    assert type(seq) == list
    ...
```

is unnecessary if the function works for any sequence type.

Lecture outline

- ★ The exception mechanism in python
- ★ Raising exceptions (`assert` and `raise`)
- ★ **Catching exceptions**

Exception handling

```
try:
    suite
except ExceptionName:
    error-handling suite
```

- ★ Execute *suite*.
- ★ If no exception arises, skip *error-handling suite* and continue as normal.
- ★ If the named exception arises from executing *suite* immediately execute *error-handling suite*, then continue as normal.
- ★ If any other error occurs, fail as normal.

* An un-caught exeception in a function causes an immediate end to the execution of the function suite; the exception passes to the function's caller, arising from the function call.
* The exception stops at the *first* matching `except` clause encountered in the call chain.

```
def f(x, y):
    try:
        return g(x, x + y)
    except ZeroDivisionError:
        return 0
    except TypeError:
        return 1
def g(x, y):
    try:
        return x / y
    except TypeError:
        return None
```

* $f(2, -2)$, $f("ab", "cd")$, $f("ab", 2)$:
  which error handler executes?

When to catch exceptions?

* Never catch an exception unless there is a sensible way to handle it.

* If a function does not raise an exception, it's return value (or side effect) should be correct.
   – Therefore, if you can't compute a correct value, raise an exception!

Bad practice (delayed error)

```
def average(seq):
    try:
        return sum(seq) / len(seq)
    except ZeroDivisionError:
        print("empty sequence!")

avg1 = average(a_seq)
avg2 = average(b_seq)
...
if avg1 < avg2:
    ...
```

* Repeat asking for input until valid:

```
number = None
while number is None:
    try:
        ans = input("Enter PIN:")
        number = int(ans)
    except ValueError:
        print("That's not a number!")
        number = None
```

⋆ Test if an operation is defined:

```
try:
    n = len(seq)
except TypeError:
    n = 0 # type doesn't have length
```

⋆ A way to check if a value is "a sequence",
  "iterable", etc. (recall these are abstract
  concepts, not actual python types).

⋆ Few cases where this is useful.

```
try:
    suite
except ExceptionName:
    error-handling suite
finally:
    clean-up suite
```

* After *suite* finishes (whether it causes an exception or not), execute *clean-up suite*.
* If an except clause is triggered, the error handler is executed before *clean-up suite*.
* If the exception passes to the caller, *clean-up suite* is still executed before leaving the function.

* Ensure file is closed even if an exception occurs:

```
def read_file(fname):
    fo = open(fname)
    try:
        for line in fo:
            # process line
    finally:
        fo.close() # close file
```

Summary

* Consider:
  - What runtime errors can occur in your code?
  - Which should be caught, and how should they be handled?
  - What assumptions should be checked?

* Use `assert` or `raise` to check violated assumptions.

* Never catch an exception unless there is a sensible way to handle it.
