### Origins

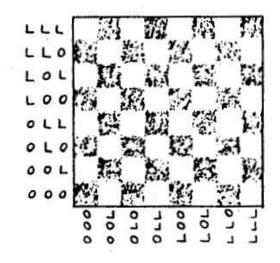

Schachtürke (Chess Turk) 1770

El Ajedrecista (The Chess Player) 1912

#### Koordinaten-Darstellung:

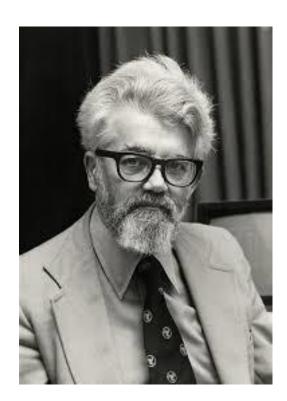

Plankalkül (Plan Calculus) 1941

# Early History of Al

John von Neumann

John McCarthy

**Arthur Samuel** 

#### Games

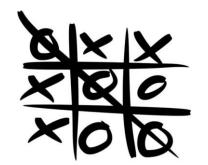

A **game** consists of a set of two or more players, a set of **moves** for the players, and a specification of **payoffs** (outcomes) for each combination of **strategies**.

#### Many different types of games:

- two-person zero-sum
- multi-player
- perfect information games
- imperfect information games
- games of chance

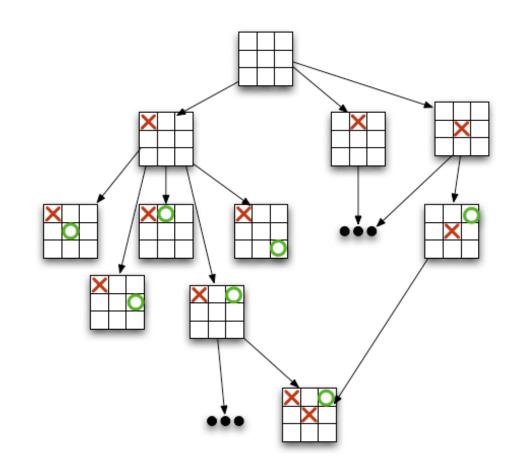

#### Game Trees

A **strategy** defines a complete plan of action for a given player.

Given enough processing time an **optimal strategy** can be found for games of **perfect information** by enumerating *paths* of a **game** tree. However, in practice this can only be done for small games.

### Minimax

Consider two players, Max and Min. Player Max is trying to maximize the score and player Min is trying to minimize the score. We assume that the players are **rational**.

#### Minimax

The **minimax** algorithm allows each player to compute their optimal move on a game tree of alternating Max and Min nodes.

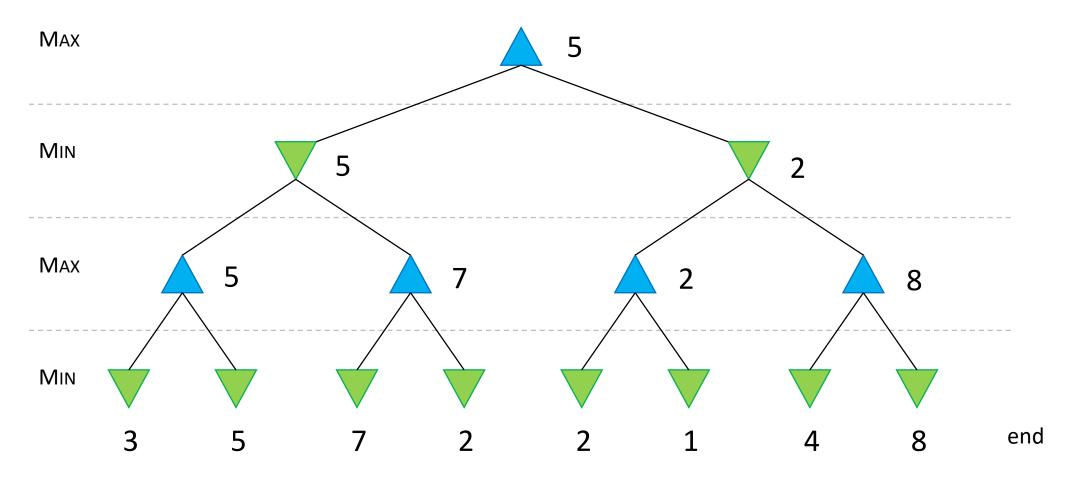

```
max-value(s)
if terminal(s) then
  return v(s)
end if
v = -∞
for each successor s' do
  v = max(v, min-value(s'))
end for
return v
```

```
min-value(s)
if terminal(s) then
  return v(s)
end if
v = ∞
for each successor s' do
  v = min(v, max-value(s'))
end for
return v
```

# Minimax Example

start

# Alpha-beta Pruning

Minimax suffers from the problem that the number of game states it has to examine is exponential in the number of moves.

Alpha-beta pruning is a method for reducing the number of nodes that need to be evaluated by only considering nodes that may be reached in game play.

**Alpha-beta pruning** places bounds on the values appearing anywhere along a path:

- $\alpha$ : the best (highest) value found so far for MAX
- $\beta$ : the best (lowest) value found so far for MIN

 $\alpha$  and  $\beta$  propagate down the game tree. The value  $\nu$  propagates up the game tree.

### Alpha-beta Pruning (2)

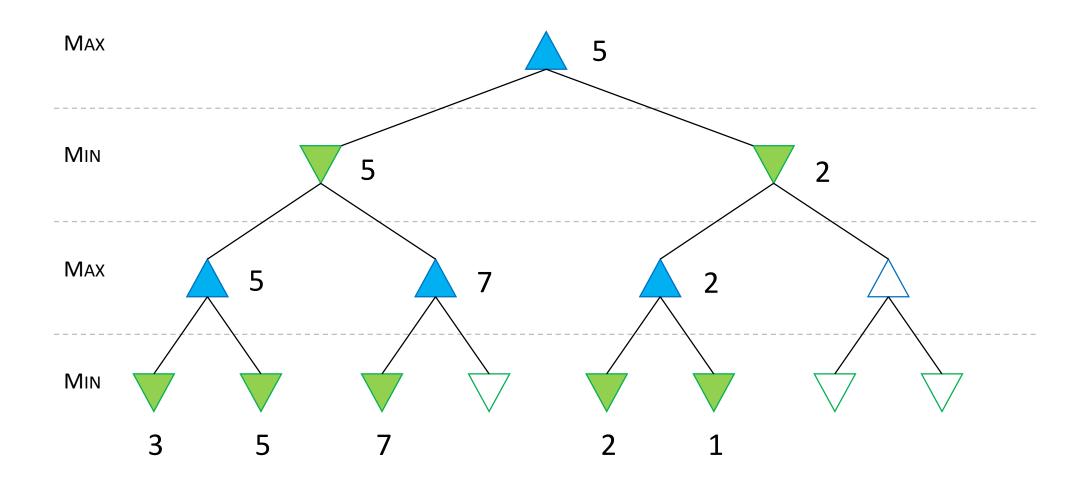

Initialize  $\alpha = -\infty$  and  $\beta = \infty$ 

```
max-value (s, \alpha, \beta)
if terminal(s) then
   return v(s)
end if
V = -\infty
for each successor s' do
   v = \max(v, \min-value(s', \alpha, \beta))
   if v \geq \beta then
     return v
   end if
   \alpha = \max(\alpha, v)
end for
return v
```

```
min-value (s, \alpha, \beta)
if terminal(s) then
   return v(s)
end if
 v = \infty
for each successor s' do
   v = \min(v, \max-value(s', \alpha, \beta))
   if v \leq \alpha then
      return v
   end if
   \beta = \min(\beta, v)
end for
 return v
```

# Alpha-beta Pruning Example

# Multi-player Games

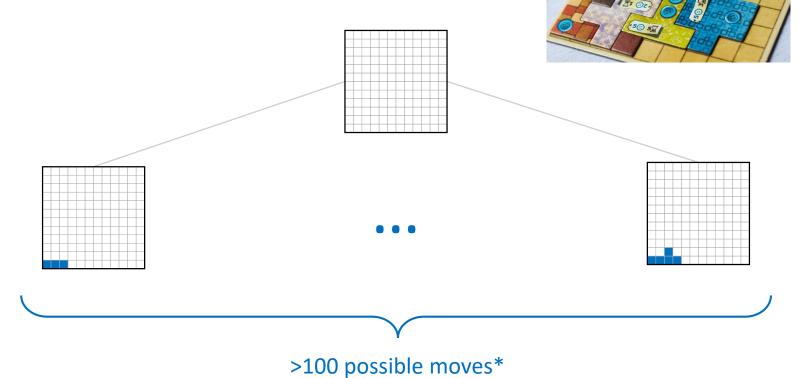

When we have more than two players we need to adapt the **minimax** approach. The most **conservative** strategy is to assume that all of your opponents are conspiring to minimize your score.

• Treat your opponents as one big powerful player.

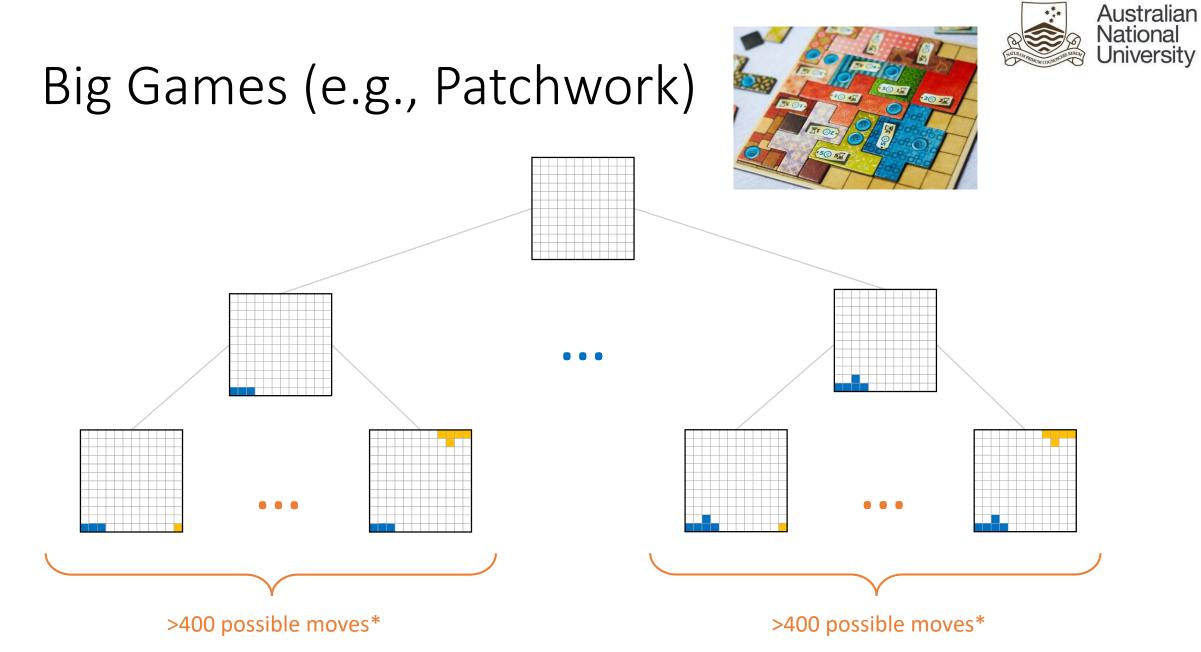

<sup>\*</sup> Depending on available pieces.

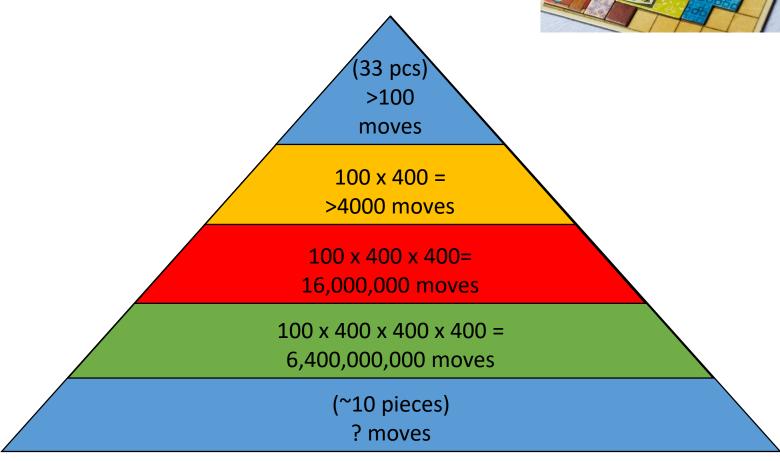

<sup>\*</sup> Depending on available pieces.

# Big Games (e.g., Patchwork)

•

#### Static Evaluation Function

For real-world games, even with **alpha-beta pruning**, we still can't search the entire game tree. In these situations, instead of a **terminal test**, we introduce a **cut-off test** that applies a heuristic value at some intermediate game state.

The heuristic is called a **static evaluation function** and it returns an estimate of the **expected payoff** from a given position.

**Machine learning** techniques are often used to find a good static evaluation function based on a linear combination of features:

$$\widehat{v}(s) = w_1 f_1(s) + \dots + w_n f_n(s)$$

### **Exploration versus Exploitation**

Learning the static evaluation function is a classic **reinforcement learning** problem.

- Repeatedly play against yourself.
- Reward board positions that lead to wins.
- Punish board positions that lead to losses.

A crucial trade off is in choosing between exploration and exploitation.

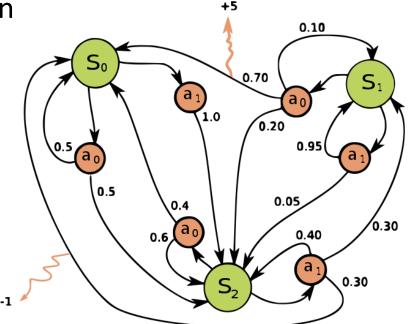

### Q-Learning

- Many games can be modelled as a Markov Decision Process:
  - At each discrete timestep, the game is in a particular state.
  - In each state, the player can choose from a set of actions.

• Given a choice of action, the system will transition to a new state chosen at random with some probability distribution.

- Q-Learning learns a 'Quality' value for each state-action combination, based on the expected reward for each state
- Parameters: learning rate, discount factor, initial Q-values

### Cut-off Test

A **cut-off test** determines when to apply static evaluation. Searching to a fixed depth is a simple cut-off policy, but this suffers from the **horizon problem**: an unavoidable damaging move that can be pushed beyond the depth of the search.

### Cut-off Test

A **cut-off test** determines when to apply static evaluation. Searching to a fixed depth is a simple cut-off policy, but this suffers from the **horizon problem**: an unavoidable damaging move that can be pushed beyond the depth of the search.

Another problem is stopping in the middle of a sequence of moves (e.g., piece exchange in chess).

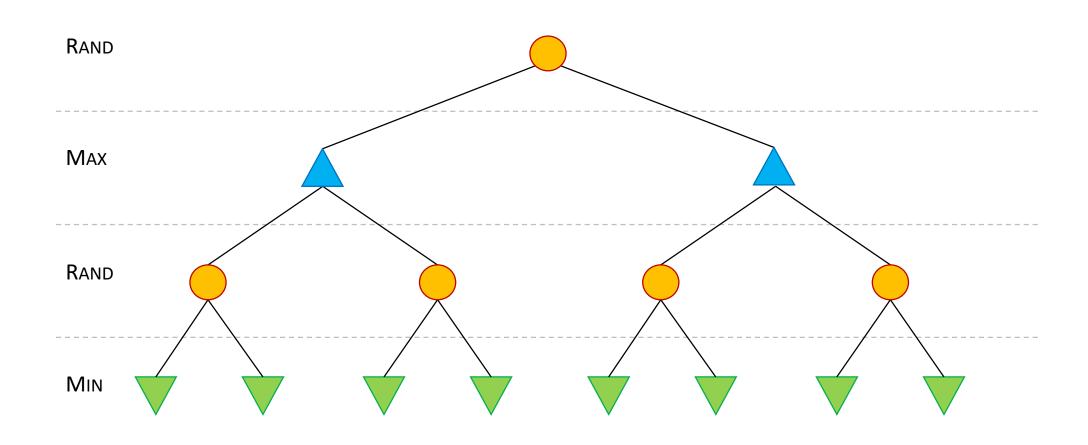

Some techniques exist to avoid these issues:

- only apply static evaluation on quiescent positions (i.e., stable heuristic).
- killer heuristic always consider bad moves from the opponent.

Games that include an element of chance require that we calculate the **expected value** of a position rather than the exact value.

### Games with Chance

# Games with Chance (e.g., Stratopolis)

#### Monte Carlo Simulation

Monte Carlo simulation is randomized algorithm that can be used to approximate the value of an intermediate game state.

- Develop the game tree to some fixed depth or some fixed width
- Run simulations from each leaf node
- Use results of simulation to assign a value to the node

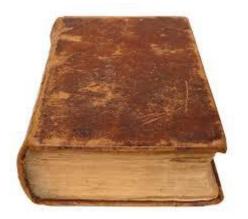

# Opening Book and Endgame Databases

- Opening books can save computation at the beginning of a game by storing a good sequence of starting moves.
  - For variety, a player can randomly choose between the moves.
  - As soon as an opponent plays a move that is not encoded in the book, the player must resort to search or simulated game play.
- For some games, the state space reduces near to the end of the game. In such cases, an **endgame database** can be precomputed by working backwards from different endings.
  - If an agent ever finds a game state that matches one in the endgame database it can immediately determined whether it will win or lose.

### Milestones in Al Game Playing

1997 IBM's Deep Blue chess machine beats Gary Kasparov

2011 IBM's Watson wins Jeopardy! requiring natural language understanding

2015 Deep reinforcement learning algorithms learn to play Atari arcade games from scratch

2016 Google DeepMind's AlphaGo beats Lee Sedol, Korea
